Screening, early detection, education, and trends for melanoma: Current status (2007-2013) and future directions

Part I. Epidemiology, high-risk groups, clinical strategies, and diagnostic technology

Jonathan E. Mayer, BA,[a,b] Susan M. Swetter, MD,[c,d] Teresa Fu, MD,[c] and Alan C. Geller, MPH, RN[a]
Boston, Massachusetts; New York, New York; and Redwood City and Palo Alto, California

Table I. Summary of new technologies for the detection of melanoma

Technology	Definition	Pros	Cons	Sensitivity	Specificity
Dermatoscopy	Examination of skin with dermatoscope	Fewer biopsy specimens and removal of benign lesions	Increases examination time and requires clinician training	90%	90%
Total body photography	Series of photographs of all skin on body	Can detect thinner tumors than the naked eye and lower biopsy rates than serial dermatoscopy	Expensive	75%	74%
Confocal microscopy	Low power laser that creates 3-dimensional image with resolution comparable to standard histology	Able to detect subclinical disease in an area wider than that of dermatoscopy	Limited by expense and the need for specialized training	90%	86%
MelaFind	Multispectral device that uses automated software for image analysis	High sensitivity	Expensive and low specificity	96-98%	0-10%
Electrical impedance spectroscopy	Device that measures changes in tissue impedance to low voltage current flow	High sensitivity	Expensive, low specificity, requires presoaking of the lesion in saline, increases examination time	98%	25-49%
Smartphone apps	Cell phone programs that analyze self-taken photographs of suspicious lesions	Widely available, and some apps send photos to Board-certified dermatologists	Experimental and highly variable quality	7-98%	30-94%

- **Dermatoscopy** increases the sensitivity of clinical evaluation for MM and has been shown to decrease the number of excised benign lesions
- **Total Body Photography** helps to detect new/thinner tumors especially in patients with numerous moles
- **Confocal microscopy** requires specialized training and may be superior to dermatoscopy for the detection of subclinical MM

DERMOSCOPY

The Impact of *In Vivo* Reflectance Confocal Microscopy for the Diagnostic Accuracy of Melanoma and Equivocal Melanocytic Lesions

Giovanni Pellacani[1], Pascale Guitera[2], Caterina Longo[1], Michelle Avramidis[2], Stefania Seidenari[1] and Scott Menzies[2]

In vivo confocal reflectance microscopy recently showed promising results for melanoma (MM) diagnosis on a limited series. The aim of the study was to evaluate the sensitivity and specificity of confocal features for the diagnosis of MM 351 equivocal melanocytic lesions (136 MMs and 215 nevi) were evaluated for 37 confocal features by two blinded expert observers. χ^2 test, multivariate discriminant analysis and binary logistic regression were performed for the identification of the significant features and for testing newly created diagnostic models. Melanomas were mostly characterized by epidermal disarray and pagetoid cells in the epidermis, non-edged papillae, and cellular atypia at the junction, and atypical nests and bright nucleated cells in the upper dermis. On the other hand, regular dermal-epidermal architecture, and absence of pagetoid infiltration and atypical cells were suggestive of benign lesions. Five out of 136 melanomas, with mildly atypical melanocytes and occasional pagetoid cells at histopathology, were not diagnosed by confocal microscopy. Nevertheless, new diagnostic models showed no significant improvement compared with the previously proposed confocal microscopy algorithm. Owing to the visualization of cellular aspects, confocal microscopy seems useful for second level examination of clinically and dermoscopically equivocal lesions.

In Vivo Reflectance Confocal Microscopy Enhances Secondary Evaluation of Melanocytic Lesions

Pascale Guitera[1], Giovanni Pellacani[2], Caterina Longo[2], Stefania Seidenari[2], Michelle Avramidis[1] and Scott W. Menzies[1]

We recently described an *in vivo* reflectance confocal microscopy (RCM) method and our aim was to evaluate a possible additive value of this type of analysis in the management of melanocytic lesions. In two referral centers (Sydney and Modena), lesions (203 nevi and 123 melanomas (MMs) with a median Breslow thickness of 0.54 mm) were excised on the basis of clinical suspicion (history, dermoscopy examination, and/or digital monitoring). The RCM method was also trialed on a non-biopsied population of 100 lesions, which were clinically and dermoscopically diagnosed as benign nevi. All RCM and dermoscopy diagnoses were performed blinded to the histopathological diagnosis. Firstly, in the study population, a high interobserver agreement (on a subset of 90 lesions) was seen with the RCM method, which had superior specificity (68%, 95% confidence interval (95% CI): 61.1–74.3) for the diagnosis of MM compared with dermoscopy (32%, 95% CI: 25.9–38.7), while showing no difference in sensitivity (91%, 95% CI: 84.6–95.5, RCM; 88%, 95% CI: 80.7–92.6 dermoscopy). The two techniques had a weak correlation, resulting in only 2.4% of MMs being misclassified by both techniques. Diagnosis of light-colored lesions is improved by RCM (specificity 84%, 95% CI: 66.3–94.5) compared with dermoscopy (specificity 39%, 95% CI: 23.7–56.2). Secondly, the RCM method classified 100% of the non-biopsied control nevi population as benign.
